Objective.— Better understanding how bimanual coordination evolves during the first weeks of natural recovery after stroke is needed. Studying kinematics of grasping movements could allow identifying how patients can be expected to benefit from bimanual rehabilitation.

Methods.— Fifteen patients were included (mean age 64.9) less than thirty days after a first unilateral ischemic/hemorrhagic stroke. Seven kinematic assessments were performed once a week for 6 weeks and a follow-up assessment 3 months after inclusion. The grasping task was performed through 3D-movement analysis in three different conditions: unimanual with the non-paretic limb (UN), unimanual with the paretic limb (UP) and bimanual (BN/BP).

Results.— We found that after 3 weeks of recovery, differences between the two hands tended to disappear, the kinematics of the paretic limb matching those of the non-paretic limb in bimanual condition. Inter-limb coordination as reflected by comparison of kinematics in bimanual movements (NPV, MT, TPV) seemed to be effective about 6 weeks after stroke. Temporal delay between hands at movement onset (ΔBEG) was constantly longer than at movement end (ΔEND).

Discussion.— These results revealed that there seems to be a period when bimanual coordination is optimized, indicating a possible beneficial effect of bimanual rehabilitation around 6 weeks after stroke. We proposed that bimanual programs could be started at the end of the second month among recovery. Moreover, inter-limb coordination was disrupted at movement onset but was preserved at movement goal. This catching up suggests that patients preserved some flexibility consecutively to the impaired temporal performance of the affected hand to achieve the end goal [1]. This disorder in limited movement initiation could be specifically retrained during rehabilitation [2].
