Preparations of the hemp plant *Cannabis sativa* have been used for medicinal purposes over centuries. THC was identified in 1964 as the predominant cannabinoid compound responsible for psychoactive effects of marijuana. Thereafter, cloning of cannabinoid receptors CB1 and CB2 in the early 1990s constituted a determinant milestone in the characterization of a novel biological system with a wide array of biological functions. Moreover, improvement in the understanding of the signaling mechanism responsible for cannabinoid actions has fostered research efforts in the development of therapeutic applications. Consequently, capsules of THC and its synthetic analog nabilone are approved in several countries for the management of chemotherapy-induced nausea and vomiting [1], and rimonabant, a selective CB1 receptor antagonist, has been available for 2 years in Europe as an adjunctive treatment of obesity or overweight with associated type 2 diabetes or dyslipidemia [2-4].
In this context, accumulating experimental and clinical data have stressed the crucial role of the cannabinoid system in the pathogenesis of non-alcoholic fatty liver disease (NAFLD). NAFLD is closely linked to the metabolic syndrome and the obesity epidemic [5], and is currently a rising cause of liver injury, with a 20-30% prevalence in Western countries. The spectrum of the disease ranges from simple steatosis, a condition generally associated with a benign liver outcome, to steatohepatitis, an entity that comprises steatosis, liver inflammation and hepatocellular injury. The latter stage is associated with activation of fibrogenic pathways and carries a 10-20% risk of cirrhosis after 10 or 20 years. As shown in several recent studies, non-alcoholic steatohepatitis (NASH) leads to increased liver-related mortality due to end-stage liver disease or development of hepatocellular carcinoma [6]. The present review summarizes evidence that cannabinoid receptor antagonism may offer novel therapeutic approaches for the management of NAFLD.

1. The endocannabinoid system

The endocannabinoid system comprises endogenous lipid ligands, specific G-protein-coupled receptors (CB1 and CB2), and proteins that are responsible for their biosynthesis, cellular uptake and degradation [7-9].

The CB1 receptor was originally cloned from a rat brain library due to its high level of expression in the central nervous system [10], and subsequent studies have shown its presence at lower levels in many peripheral tissues. Expression of CB2 receptors predominates in the immune system and, although more restricted, is increasingly demonstrated in several cells [8,11,12]. Recent reports also suggest the existence of additional cannabinoid receptors.

Endocannabinoids are hydrophobic fatty-acid-derived compounds with predominantly autocrine/paracrine effects, among which anandamide (arachidonoyl ethanolamide) and 2-arachidonoyl glycerol (2-AG) are the best known. Both compounds are synthesized on demand and are rapidly degraded by fatty-acid amide hydrolase (FAAH) or monoacylglycerol lipase, following ligand binding and cellular reuptake [8,9,11,12]. Anandamide shows a higher affinity for CB1 than CB2 receptors and is therefore considered a major endogenous CB1 ligand, whereas 2-arachidonoyl glycerol binds both receptors with similar affinity [13]. In addition, both compounds also induce CB1- and CB2-independent effects. Lipid mediators other than anandamide and 2-AG have been reported to bind CB receptors, but their biological significance remains undetermined.

2. Modulators of cannabinoid receptors as therapeutic agents

Rimonabant has been the first CB1 antagonist to reach the market in Europe [2-4]. The drug was initially developed for the treatment of obesity in light of the positive impact of phyto- and endocannabinoids on central appetite-regulating pathways. It soon became clear that CB1 antagonism produces metabolic effects beyond those expected from weight loss alone, including improvements in dyslipidemia, insulin resistance and diabetes [14]. In keeping with clinical data, experimental studies have established that multiple peripheral mechanisms contribute to the beneficial effects of CB1 antagonism by enhancing energy expenditure, peripheral lipolysis and insulin sensitivity, among others [15,16]. Accordingly, trials are underway to further define the impact of CB1 antagonism on dyslipidemia, type 2 diabetes and cardiovascular morbidity. Other therapeutic applications under evaluation also include management of alcohol- and nicotine-dependence or neurodegenerative disorders [9]. The safety of CB1 antagonists in obesity has been questioned, given the occurrence of modest rates of anxiety and depression in susceptible individuals [14]. As a result, the FDA denied approval of rimonabant pending additional data, whereas Merck recently suspended the development of taranabant for obesity due to safety concerns. In this context, the development of peripherally restricted CB1 antagonists could prove of interest by avoiding central adverse effects.

Although selective agonists and antagonists of CB2 receptors have not yet reached a clinical stage, preclinical studies nevertheless suggest meaningful therapeutic applications as anti-inflammatory, analgesic or anti-allergenic compounds [9,17]. Of particular interest, such compounds should be devoid of central adverse effects.

Identification of cannabinoid receptors as potential therapeutic targets for the management of liver diseases [7] has emerged recently with the demonstration that CB1 receptors contribute to the pathogenesis of cirrhotic portal hypertension [18,19]. Soon after, additional studies uncovered a key role of cannabinoids in metabolic and ethanol-induced fatty liver, ischemia reperfusion, and in the scarring process associated with chronic liver disease [20-25].

3. Pathogenesis of NAFLD

It is now admitted that metabolic steatosis and insulin resistance are in tight relationship [26]. Thus, rodent models have shown that resistance to insulin promotes lipolysis in adipose tissue, thereby increasing delivery of free fatty acids to the liver [26]. Moreover, in the liver, hyperinsulinemia triggers de novo fatty acid, and impairs β-oxidation and lipid dis-
posal. Conversely, however, steatosis may also contribute to hepatic insulin resistance [26]. The transition from steatosis to NASH is poorly understood and appears to be multifactorial. Excess accumulation of free fatty acids leads to increased oxidative stress and lipid peroxidation, thereby resulting in cellular injury. Moreover, enhanced cytokine production by infiltrating macrophages in adipose tissue and the liver are also incriminated in the progression of injury [5].

4. Cannabinoid receptor antagonism reduces development of NAFLD

4.1. CB1 receptors promote metabolic steatosis and insulin resistance

Recent findings have shown that the hepatic cannabinoid system is activated in NAFLD. Thus, in the experimental model of diet-induced obesity, hepatic anandamide levels are increased following inhibition of its degradation by FAAH, and CB1 receptor expression is strongly induced in hepatocytes [23].

Accumulating experimental evidence indicates that CB1 receptors contribute to metabolic steatosis and the related insulin resistance [23,24,27]. CB1 receptor knockout mice are resistant to high-fat diet (HFD)-induced obesity and steatosis, and to the associated increase in hepatic lipogenesis; moreover, HFD-fed CB1-ablated mice display reduced insulin resistance [23,28]. In keeping, genetically obese fa/fa rats treated with rimonabant show reversal of hepatic steatosis and improved insulin sensitivity [27]. Interestingly, mice bearing a selective deletion of CB1 receptors in hepatocytes become obese under a HFD, but are protected from hepatic steatosis [29]. CB1 receptor expression is strongly induced in hepatocytes [23]

4.2. CB receptors regulate liver fibrogenesis

As stated previously, transition from steatosis to NASH is associated with activation of fibrogenic pathways and predisposes to the development of liver fibrosis [32]. We recently found that expression of CB1 and CB2 receptors is markedly upregulated in cirrhotic liver samples, predominantly in liver fibrogenic cells, and demonstrated that CB1 and CB2 receptors display potent pro- and antifibrogenic properties, respectively [22,25]. Antifibrogenic properties of CB2 receptors were established in CB2 knockout mice repeatedly exposed to carbon tetrachloride, based on findings that these mice show enhanced liver fibrosis and increased accumulation of liver fibrogenic cells compared with wild-type animals [22]. The function of CB1 receptors in liver fibrogenesis was assessed in three different experimental models (chronic carbon tetrachloride or thiacetamide administration and bile duct ligation). Administration of rimonabant or genetic inactivation of CB1 receptors significantly reduced progression of fibrosis [25]. Profibrogenic properties of CB1 receptors were ascribed to the overactivation of CB1 receptors expressed by liver fibrogenic cells, leading to a combined enhancement of cell proliferation and decrease in apoptosis rate.

The clinical relevance of these experimental findings was confirmed in an epidemiological study of the impact of cannabis use on fibrosis severity in HCV-infected individuals. Daily cannabis use was documented as an independent predictor of fibrosis severity, suggesting that CB1 signaling dominates over CB2 during chronic hepatitis C [33]. A subsequent independent study in a Canadian cohort reported similar findings [34].

5. Emerging role of CB2 receptors in the pathogenesis of NAFLD

Several studies have shown that obesity generates a low-grade inflammatory state that contributes to the development of insulin resistance and NAFLD [35-37]. CB2 receptors are potent regulators of innate immunity [38] and we recently investigated their potential role in the pathogenesis of NAFLD. Compared with wild-type counterparts, mice invalidated for CB2 receptors are less prone to HFD-induced obesity [39].
Moreover, CB2 knockout mice are resistant to steatosis and display improved glucose tolerance. The mechanism underlying steatogenic effects of CB2 receptors appears to involve proinflammatory effects of upregulated CB2 receptors in adipose tissue.

6. Conclusion

Accumulating data indicate that the endocannabinoid system is upregulated in NAFLD and plays an important role in the pathogenesis of steatosis and insulin resistance via peripheral pathways. CB1 antagonism has proven efficient in the control of experimental NAFLD and liver fibrogenesis. Recent clinical trials have also established that inactivation of CB1 receptors not only reduces overweight, but also improves several parameters of the metabolic syndrome, including insulin resistance and dyslipidemia [14]. These observations undoubtedly provide a strong rationale for the evaluation of CB1 antagonists in the management of NASH, as currently underway in phase III clinical trials. Concern over potential adverse central effects of CB1 antagonists should stimulate ongoing efforts to develop peripherally restricted molecules.
