Keywords: Mirror therapy; Spatial neglect; Stroke

Objective.– A few studies have suggested an effect of mirror therapy on hemiparesis after stroke (CVA) [1]. Recent work has also suggested a long-term effect on spatial neglect [2]. Our objective was to evaluate the immediate effect of a single session of mirror therapy on manifestations of spatial neglect.

Patients and methods.– We included eight subjects (30-75 years) with spatial neglect (according to Negligence Evaluation Battery) secondary to a unilateral stroke of the right hemisphere. Mirror therapy sessions lasted for 30 minutes and used the classic mirror therapy device [1] with a cache on the right upper limb. Control therapy used the same device and reproduced the visual anchor to the left space for the same duration. However, the image of the right arm was replaced by landscape images. The effect of the two procedures was compared in a randomized cross-over protocol with a wash out period of one week. Patients were evaluated blindly, before and after each session, by a line bisection test and a cancellation test. Statistical analysis used the nonparametric Wilcoxon test with an alpha risk of p = 0.05.

Results.– Mirror therapy induced a significant improvement in line bisection test (p = 0.025) but not in cancellation test. Control therapy had no effect on performance in any test. However, no significant difference was observed between the effects of two therapies.

Discussion.– Mirror therapy is applicable to subjects with spatial neglect under certain conditions. Immediate efficiency seems to be present but only partially. This result supports the hypothesis of an effect of mirror therapy on spatial neglect [2]. The effect appears to be independent of the attentional component. The induced effect may result from right hemisphere activation in relation to the visual illusion of upper left limb movement.

Background.– Hemineglect is a syndrome characterized by disturbances of space exploration to the left hemifield with behavior of deviation to the right. Due to the diversity of its manifestations and brain lesion responsible for symptoms, pathophysiology, diagnostic and therapeutic still remain problematic. We have implemented on a computer interface the bells cancellation test (Gauthier 1999).

Objective.– Establish the effects of striking targets (global or predominantly on the left) with color and/or movement on visual exploration according to each condition. Immediate efficiency seems to be present but only partially. This result supports the hypothesis of an effect of mirror therapy on spatial neglect [2]. The effect appears to be independent of the attentional component. The induced effect may result from right hemisphere activation in relation to the visual illusion of upper left limb movement.

between two targets versus 3.8 seconds between two targets, \( P < 0.001 \) or by motion (3.2 seconds versus 3.9, \( P < 0.001 \)). Moreover, the introduction of a left lateralized pop-out effect improves speed of execution in left hemifield, and therefore surpasses the spatial bias law. The pop-out effect persists among hemineglect patients in the right as well in the left hemifield.

Since the pop-out effect allows hemineglect patients to surpass their spatial exploration bias, we suggest that rehabilitation exercises via this computerized form, could help patients to manage their disorder.
