week with a facultative mild intensity continuous session. Body composition, blood analysis, cognitive performances, maximal exercise tolerance with gas exchange analysis, non-invasive cardiac output measurement and Near-Infrared Spectroscopy (NIRS) cerebral signals were measured before and after training. Results.— We found significant improvements in maximal power and VO2max, a decrease in maximal heart rate without other hemodynamic changes. Weight, BMI, fat mass, and waist circumference significantly decreased (P < 0.01), whereas no effects on biological parameters, nor on muscle mass were observed. Some cognitive tests for executive functions (Digit Symbol Substitution Test, P < 0.01; Digit span, P < 0.05) and memory (Rey Auditory Verbal Learning Test, P = 0.03) significantly improved. Regarding the kinetics of the NIRS signals during exercise, both deoxyhemoglobin (HHb) and hemoglobin difference between oxy- and deoxyhemoglobin (HbDiff) had higher amplitudes after training (P < 0.05).

Conclusion.— In addition to improvements in exercise tolerance, a program combining HIIT and resistance training could improve executive functions in overweight adults. These results were associated with changes in cerebral oxygenation measured using NIRS.

Objective.— To measure the impact at 2 months time of stationary bike home training on fatigue among under 50 years old multiple sclerosis patients [1].

Methods.— A multicentre non-randomized pilot study evaluating the feasibility of home stationary bike training was conducted. Patients with MS, complaining of predominant physical fatigue, less than 50 years old, without cardiovascular contra-indications, with an EDSS, without cognitive impairment, or relapse in the last 3 months were included. Patients with musculoskeletal, neurological or cardiovascular impairment not allowing stationary cycling, or without any interest for reconditionning program were excluded. The intervention was a short educational session (one hour time) to use stationary bike (home delivery) at first ventilatory threshold, 25 min per session, 3 sessions per week for 8 weeks long. The primary endpoint was fatigue [2] (EMIF), secondary endpoints qualitative and quantitative compliance, walking speed (7.5 m test) and endurance (6 min walk test), health-related quality of life (SF-36). The number of subjects required was 30. Results 25 patients was finally included and analysed. Home stationary bike program, allowed a significant improvement of fatigue on the total EMIF, walking speed and endurance, without significant effect on the quality of life.

Discussion.— This study demonstrated the feasibility of home stationary bike reconditionning with limited supervision. The main limitations are lack of control group, a limited number of subjects, and low EDSS at baseline. In absence of monitoring, long term effect still unknown.
