A prospective, monocentric study. Generalized diffusion has been searched with a single fiber EMG (or Neuromuscular Jitter) on striated muscles away from BoNTA injected muscles. Neuromuscular jitter (NMJ) is compared between 16 patients with unusual fatigue after BoNTA injection, 17 asymptomatic patients treated with BoNTA (control group), 19 patients suffering botulism-like syndrome having muscular deficit distant from BoNTA injection site and three patients suffering botulism food poisoning. Indications were treatment of neurogenic detrusor overactivity or spasticity. NMJ is the gold standard for evaluating neuromuscular junction dysfunction. Mean jitter, percentage of pathological fibers and number of conduction blocks are compared between groups.

Results.– Mean jitter, percentage of pathologic fibers and conduction blocks for asymptomatic patients differs from those of patients presenting distant muscular deficit (P = 0.0001) and patients suffering botulism (P = 0.017). Mean jitter and number of conduction blocks differ between patients presenting unusual fatigue and patients presenting distant muscular deficit (P = 0.0005). No significant difference appears between asymptomatics and patients relating unusual fatigue after BoNTA treatment.

Discussion.– This study doesn’t give rise to generalized BoNTA diffusion in patients reporting unusual fatigue after BoNTA treatment although jitter clearly differs between patients presenting distant muscle weakness and control group. Generalized neuromuscular disorder doesn’t seem to explain those fatigue events. Several hypotheses can account for it: not enough patients in the group reporting unusual fatigue, fatigue could be due to autonomic nervous system disorder that is not explored with this single fiber EMG, immune mechanism. Fatigue could be reported to initial disease.

Biomechanical, clinical and gait analysis’ effects of BoNTA injection in the rectus femoris muscle of incomplete SCI patients

Hôpital Leon-Berard, avenue du Dr-Armanet, BP 10121, 83400 Hyères, France

CHU Raymond-Poincaré, France

A prospective open pilot study. n = 15 incomplete SCI patients, impaired by a specific RF spasticity (n = 20), with RF hyperactivity in mid-swing and a stiff-knee-gait quantified by formal Gait Analysis (GA), were assessed before and after BoNTA injection (Botox, 200 UI). Main outcome

Effect of botulinum toxin injection in rectus femoris in stroke patients with stiff knee gait: Analytical effect and in gait re-organization

Keywords: Stroke; Spasticity; Botulinum toxin; Motion analysis; Isokinetic dynamometer

Objective.– Over the past few years, several studies have shown that a botulinum toxin (BTX-A) injection in the rectus femoris muscle (RF) could enhance stroke patients’ walking capacity (Robertson et al., 2009). However, the mechanisms behind these benefits are still unknown. The aim of this study was to compare the analytical effect of BTX-A in the RF muscle (passive stretch and voluntary strength assessed by an isokinetic dynamometer) and functional repercussions on gait (assessed by three-dimensional motion analysis) in spastic hemiparetic patients with stiff knee gait (SKG) caused by RF spasticity.

Methods.– Ten stroke patients with SKG caused by RF spasticity were included and evaluated before and after a BTX-A injection in RF. Analytical evaluations consisted of: (i) a clinical examination; (ii) an assessment using an isokinetic dynamometer with surface electromyography (in order to quantify passive stretch and knee flexor and extensor voluntary strength; (iii) a three-dimensional motion analysis gait assessment (in order to quantify spatiotemporal and kinematic gait parameters).

Results.– One month after BTX-A injection in RF, the following results were found: (i) a decrease in knee extensor strength and an increase in knee flexor strength; (ii) no change in the intensity of extensor activity during passive stretch; (iii) an increase in the angle at which the stretch reflex occurred. 3D analyses showed an increase in gait speed, which was related to an increase in cadence and an increase in peak knee flexion during swing phase.

Discussion.– The improvement in knee flexion following BTX-A injection in RF seems to be related to an increase in the angle at which the stretch reflex occurs with no change in intensity of the contraction. This change in the threshold of the sensitivity of neuromuscular spindles infers that BTX-A affects the motoneuron γ-neuromuscular spindle synapse (Trompetto et al., 2006).

measures included peak torque (and angle at peak torque) of the quadriceps at different hip positions (0°, 90°) and velocities during passive stretch (10°/s, 90°/s, 150°/s) and voluntary contraction (60°/s). Secondary outcome measures included impairments (Modified Tardieu Scale (MTS), peak knee flexion and spatial-temporal data on GA), activity (6 min. walking test, timed stair climbing), and discomfort (“discomfort Verbal Rating Scale”).

Results.—Highly significant effects of velocity ($P < 0.0001$) and hip positions ($P < 0.01$) on stretch reflex-related torque confirmed the clinical hypotheses (spasticity > contracture, RF' prevalence among quadriceps spasticity). After BoNTA injection, voluntary torque decreased ($-16\%$, $P = 0.0004$) but with only a trend toward a decrease in stretch reflex-related torque. The angle at spastic torque increased ($+5^\circ$ at 90°/s; $P = 0.03$) along with improvement in MTS, peak knee flexion ($+4^\circ$, $P = 0.01$), spatial-temporal data, and timed stair climbing test (25%; $P = 0.02$).

Discussion.—The authors discussed the lack of a spastic torque decrease, and the clinical relevance of a small peak knee flexion increase in potentially improving the stair climbing task.

Conclusion.—BoNTA appeared to delay the stretch reflex angle at peak torque, whereas the voluntary torque decreased. After strict patient selection, BoNTA injection into the RF muscle led to improvements in impairment, activity and discomfort.
