Placebo and nocebo effects in pain treatment: Clinical implications
J. Bruxelle
Fondation Ophtalmologique Adolphe-de-Rothschild, Paris, France

Keywords: Placebo effect; Nocebo effect; Pain treatment
The placebo, when prescribed with an analgesic intent, induces a placebo effect that often mimics the analgesic properties of a tested drug in clinical trials. Real psycho-neurophysiological event, this placebo effect is influenced by patient’s expectations and past experiences, doctor’s convictions and suggestions, and the doctor-patient relationship. It results from activation of several pain control systems, mainly opioid and dopaminergic. Nevertheless, in some cases, the prescription of a placebo or analgesic drug can be followed by pain increase without worsening of disease. This nocebo effect is often observed when the patient has negative expectations: – fear of drug and its side effects influenced by negative past experiences or anxiogenic information; – or when the doctor-patient relationship is poor. This hyperalgesic nocebo effect could mainly result from activation of cholecystokininergic systems facilitating the transmission of painful messages.

Emotion and neuropathic pain
G. Mick
UETD, Voirin, France

Keywords: Emotion; Neuropathic pain
The pathophysiology of neuropathic pain suggests that clinical symptoms fluctuate with emotional state in patients, a hypothesis that seems verified by clinical practice. We will review arguments in favor of an emotional modulation of the neuropathic clinical picture, which might shed light for mechanisms of action in non-pharmacological therapeutic approaches, such as hypnosis or cognitivo-behavioral therapy.

Keywords: Conditioned pain modulation; Expectation; Nociceptive flexion reflex
Introduction. – Impaired conditioned pain modulation is common in chronic pain conditions and may increase the risk of persistent postoperative pain. The aim of this study was to determine if manipulating the expectation of pain inhibition can enhance conditioned pain modulation.

Methods. – In 19 healthy males, the lower limb nociceptive flexion reflex was elicited in isolation (test stimulus) and during application of two forms of painful conditioning stimuli. Following application of the first conditioning stimulus (CS1), the participants were informed that the subsequent conditioning stimulus (CS2) would elicit a greater amount of inhibition of test pain compared to the first. Lower limb flexion reflex size, perceived pain ratings of the test stimulus, and ratings of expected pain modulation were measured.

Results. – Pain inhibition was significantly greater with CS2 compared to CS1 (P = 0.003); however, there was no significant difference in inhibition of nociceptive flexion reflex size (P = 0.8) between the two conditioning stimuli.

Discussion. – These findings suggest that cognitive suggestion led to inhibition of nociception at a supraspinal level without influencing spinal nociceptive processing. The finding that conditioned pain modulation can be enhanced with cognitive suggestion may be relevant in the prevention and treatment of chronic pain.

Keywords: Music therapy; Nociceptive flexion reflex
Introduction. – Chronic pain is a highly prevalent condition that can lead to significant suffering and functional impairment. Music therapy has been shown to be effective in the management of chronic pain.

Methods. – The current study aimed to evaluate the effectiveness of music therapy on pain outcomes in patients with chronic pain. Patients were randomized to receive either music therapy or usual care.

Results. – Patients who received music therapy reported significant reductions in pain intensity and disability compared to those in the usual care group.

Discussion. – Music therapy appears to be a viable and effective intervention for the management of chronic pain.
